PRACA DYPLOMOWA

Communication algorithms and principles for a prototype of a wireless mesh network

Autor: Sergiusz Urbaniak

Opiekun pracy: dr inż. Remigiusz Olejnik

Oświadczenie

Oświadczam, że przedkładaną prac magisterską/inżynierską kończącą studia napisałem samodzielnie. Oznacza to, że przy pisaniu pracy poza niezbędnymi konsultacjami, nie korzystałem z pomocy innych osób, a w szczególności nie zlecałem opracowania rozprawy lub jej części innym osobom, ani nie odpisywałem rozprawy lub jej części od innych osób. Potwierdzam też zgodność wersji papierowej i elektronicznej złożonej pracy. Mam świadomość, że poświadczenie nieprawdy będzie w tym przypadku skutkowało cofnięciem decyzji o wydaniu dyplomu.

Software Algorithms

5.1. Module orchestration

Designing a software system that executes on embedded micro-controllers implies a lot of challenges when many software modules are involved and complexity grows. The conceptually defined modules must be somehow implemented. If the micro-controller lacks an operating system then there is no possibility of using provided abstractions and APIs for module orchestration and execution. Another challenge are limited hardware resources which prevent the deployment of many existing operating system kernels. Basically there are two types of execution models which can be implemented in micro-controllers:

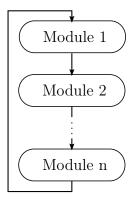

Figure 5.1. Sequential execution model

1. Sequential execution model: This type sequentially executes all modules

inside an infinite main loop starting from the first module until the last one. Once the last module ends the execution starts again from the first module.

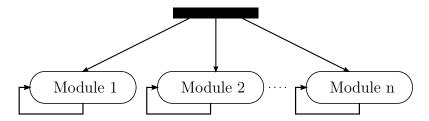

Figure 5.2. Concurrent execution model

2. Concurrent execution model: This type executes modules concurrently. Instead of having an infinite main loop that iterates sequentially over all modules the main function only initializes and launches concurrent modules.

5.1.1. Sequential execution

This model does not necessarily needs operating system support or frameworks. It can be simply implemented as a sequence of function calls inside an infinite loop as shown in algorithm 1.

Algorithm 1 Sequential model algorithm while true do $module_1$ $module_2$... $module_n$ end while

There is one challenge that comes with this type of execution model. That is that only one module can execute at a time due to its sequential nature. If a module i.e. waits for an external resource to provide data it must not block the execution of the main loop until the external resources becomes ready. This would prevent the execution of the other modules. The classic solution to this problem is the introduction of states in modules. Module states can be implemented as classical Finite State Machines ([1]).

If we take the example from above about waiting for external resources a finite state machine for modules can be modeled as shown in figure 5.3.

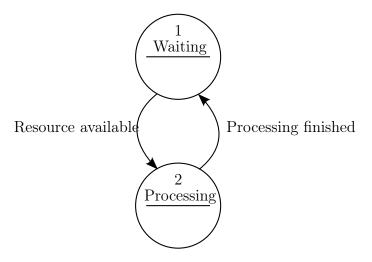

Figure 5.3. State Machine for a module

State machine models can be implemented using if or case statements which is shown in algorithm 2. The nice side effect of a state machine based implementation is the non-blocking nature of the module execution. Take for instance the execution of state 1 "Waiting" as shown in figure 5.3. The CPU only needs to execute as many instructions as are necessary to check if the awaited resource is available. If the resource is not available the execution returns to the main loop and the next module (together with its state machine) is being executed.

Algorithm 2 State machine algorithm

```
if state is WAITING then

if resource is available then

set state to PROCESSING

else

exit module

end if

else if state is PROCESSING then

process data

set state to WAITING

end if
```

This implementation emulates a concurrent execution of modules. The context switch between module executions is being done by the modules themselves (using self-interruption) and no external scheduler is involved. This form of concurrent behavior can therefore be described as a non-preemptive or cooperative multi-tasking between modules. The predecessor thesis [2] implementation heavily used the described state machine algorithm although the model theory behind the implementation was not being mentioned in the thesis. Listing 5.1 shows the main function of the predecessor thesis implementation.

Listing 5.1. main function implementation in [2]

```
382 while (0x01)
383 {
384
            if(uartInterrupt == ON) // got a character from RS232
385 +--- 44 lines:
429
430
            // --- RECEIVE A DATAGRAM ---
431
432
433
            else if((datagramReceived = datagramReceive(...))
                     && netState > 0)
434 +----182 lines:
616
617
            else if(helloTime) // prepare periodic Hello message
618
619 +--- 19 lines:
638
639
640
            // --- SEND A DATAGRAM ---
641
642
```

A couple of problems arise from the existing implementation. First of all listing 5.1 reveals the following modules:

- UART Module
- Datagram Receiver Module
- Hello Message Sender Module
- Datagram Sender Module

Which module is being executed depends on the state of the main module being represented by the main function. The state of the main module on the other hand depends directly from the state of the submodules. The main module therefore acts more like a controller of the submodules and takes away the responsibility of the submodule's state management. Furthermore the main function is very long and complex (271 lines of code). The lack of a clear separation of module responsibility and conformance to the state machine theory led me to a completely new implementation as show in listing 5.2.

Listing 5.2. main function implementation

```
95 while (true) {
96    shell();
97    batman_thread();
98    rx_thread();
99    uart_tx_thread();
100    watchdog();
101    timer_thread();
102 }
```

The new implementation makes it very clear which modules are being executed sequentially. Furthermore the main function does not act as a controller but rather leaves the state management in the module's responsibility.

There is a problem though in state machine based implementations and that is the rapidly growing complexity. This problem is called "state explosion problem" and has even a exponential behavior as shown in [3]. The equation 5.1 shows that the number of states is dependent on the number of program locations, the number of used variables and their dimensions.

$$\#states = |\#locations| \cdot \prod_{variable \ x} |dom(x)|$$
 (5.1)

This equation shows that for instance a program having 10 locations and only 3 boolean variables already has 80 different states. Although this equation might not apply exactly to state machine based implementations it underlines the practical experience of big state-machine based implementations. The alternative to state-machine based applications are thread or process based implementations using the concurrent execution model as shown below.

5.1.2. Concurrent execution

This model requires support from an existing operating system. An existing framework or API provides the necessary abstraction to create new concurrent modules. Each module runs in isolation and can have its own main loop or terminate immediately. In terms of operating systems two abstractions are widely used for concurrently running software modules:

- Processes: Processes are usually considered as separately concurrently running programs. Usually each process owns its own memory context and communication with other processes happens through abstractions like pipes or shared memory.
- Threads: Threads are concurrently running code parts from the same program.

The initial program is considered to run in its own "main thread". Other threads can be started from the main thread. Threads also do run in isolation to each other. Each thread has its own stack. Communication with other threads happens through shared memory provided by static data or the heap.

Processes as well as threads are widely known concepts in classical desktop operating systems. In the area of embedded micro-controllers these concepts also are implemented in many different implementations:

```
1. FreeRTOS (http://www.freertos.org)
```

```
2. TinyOS (http://www.tinyos.net)
```

- 3. Atomthreads (http://http://atomthreads.com)
- 4. Nut/OS (http://www.ethernut.de/en/firmware/nutos.html)
- 5. BeRTOS (http://www.bertos.org)

The above solutions have chosen different names for threads or processes (some call them "tasks") but essentially they all share the same concept of the concurrent execution model and will be referred to as concurrent modules from now on. Algorithm 3 shows the pseudo-code that initializes concurrent modules. One can see that in contrast to the sequential execution model the main loop actually does nothing.

Algorithm 3 Concurrent model initialization

But how does a context switch happen between concurrent modules? Two methodologies exist:

- Cooperative: The concurrent modules by themselves return the control to a scheduler which then delegates the control to a different module. Which concurrent module gets control is often based on priorities which are controlled by the scheduler.
- **Preemptive**: Here the concurrent modules do not have control about how and when they get interrupted. It can happen anytime during the execution. Again the context switch between concurrent modules is often handled using priorities in the scheduler.

Nearly all existing solutions have one feature in common. That is that every thread has its own separate stack memory space. This is necessary in order to be able to run the same block of code (for instance a function) in multiple thread instances. On the other hand threads are being executed in the same memory context so sharing data between threads is possible by using the heap or static memory. All of the above mentioned frameworks provide common abstractions which are needed in thread based implementations:

- Semaphores
- Mutexes
- Yielding

In contrast to state machine based or sequential based concurrency thread based implementation can be expressed in very linear algorithms using the above mentioned abstractions. Take for instance the state-machine based algorithm 2. This could be translated into a linear thread-based algorithm as shown in 4.

Algorithm 4 Thread based algorithm

while true do

wait for resource mutex

process data

release resource mutex

end while

One can easily see that the thread-based algorithm 4 is much more expressive than the state-machine based algorithm 2.

Together with the necessity of having a scheduler these solutions can be considered as heavy-weight. The scheduler consumes additional CPU cycles and the separate stack memory space per thread consumes additional memory which is very scarce in embedded micro-controller systems.

Although usually a concurrent execution model must be provided in form of an API or an existing kernel there is one exception in the context embedded micro-controllers and that are ISRs (Interrupt Service Routines). Interrupt service routines behave like preemptive concurrent modules with highest priority.

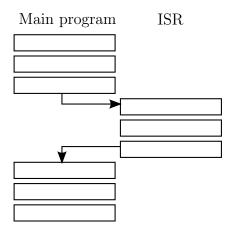

Figure 5.4. Illustration of an Interrupt Service Routine

The ISR interrupts the main program at any time when an external resource triggers an event and executes the service routine. The scheduler in this case is the CPU itself. There is one caveat with ISRs. When one ISR is being executed no other ISR can be triggered. Therefore it is being considered best practice not to perform intense and long running operations in ISRs.

5.1.3. Conclusion

For the implementation of this thesis the following conclusions were drawn:

• Existing solutions supporting the concurrent execution model were considered too heavy-weight for this type of application. Although 32KB of RAM are available

the purpose is the support of route storage and network support.

 A sequential execution model was favored instead of the concurrent execution model. On the other hand thread-like linear algorithms are definitely favored instead of state machine based implementations which could lead to a state explosion.

One framework exists which implements the sequential execution model but providing a linear thread-like API being called Protothreads as described in [4]. It is implemented using C macros and expands to switch statements (or to goto statements if the GCC compiler is being used). Instead of consuming a complete stack per thread the protothread implementation uses only two bytes per (proto)thread. Protothreads actually are stackless and variables initialized on the stack of a protothread function will stay initialized only during the very first call of the protothread.

```
Algorithm 5 Simple linear algorithm

while true do

wait until timer expired

process data
end while
```

Algorithm 5 shows a very simple linear use case where it waits for an external resource. In this case it waits for the expiration of an external timer by merely watching the timer's state. Since this is a read-only operation no explicit mutual exclusion is needed. This algorithm expressed as a protothread implementation is shown in listing 5.3.

Listing 5.3. linear protothread implementation

```
19 PT_THREAD(test(void))
20 {
21   PT_BEGIN(&pt);
22   PT_WAIT_UNTIL(&pt, timer_ready());
23   process_data();
```

```
24 PT_END(&pt);
25 }
```

The implementation of the algorithm is self-describing and corresponds to the APIs known from the concurrent execution model. The expanded version of the listing after the preprocessor stage is seen in 5.4.

Listing 5.4. expanded linear protothread implementation

```
char
test(void)
{
  // PT_BEGIN
  switch((&pt)->lc) {
    case 0:
      // PT_WAIT_UNTIL
      do {
         (\&pt) -> 1c = 22;
    case 22:
         if(!(timer_ready())) {
           return 0;
         }
      } while(0);
      process_data();
  // PT_END
  };
  (\&pt) -> 1c = 0;
  return 3;
}
```

```
Listing 5.5. UART module sending function from thesis [2]
void rsSend(uint8_t data)
{
  while( !(UCSRA & (1<<UDRE)));
  UDR = data;
}</pre>
```

The expanded version after the preprocessor stage of the implementation looks much more like a state machine based implementation from the sequential execution model. It uses a clever trick called loop unrolling ([5]) which breaks ups the while statement using the switch statement. This technique is also known as Duff's device as described in [6]. Unfortunately this implementation has one drawback. One cannot (obviously) use switch statements in protothreads. A slightly more efficient implementation using GCC labels circumvents this. Since the context switch is managed by the concurrent modules themselves the behavior can be classified as *cooperative* multitasking.

Due to the lightweight nature of protothreads and the possibility to express algorithms in a linear thread-like fashion this framework was chosen by the author for the implementation.

5.2. Ring Buffers

The predecessor thesis [2] used the UART interface in order to communicate with the user and to inform about incoming packets, changes to routes, etc.. As already analyzed in the previous chapter a state machine based sequential concurrent model was used to implement the UART module. There exists one problem with the current implementation.

Listing 5.5 shows that the algorithm examines the UCSRA (USART Control and Status Register A) and blocks infinitely until the UDRE (USART Data Register Empty) bit becomes zero. The execution of all other concurrent modules and the main loop will be blocked until the UART becomes ready to accept data. In this time period no data can be received from the radio. The above mentioned implementation uses the same function for sending strings via the UART interface. For sending the

string "hello" via the UART with a speed of 19.2kbps the main loop will be physically blocked for 2.5 milliseconds. In order to improve the implementation the author wanted to accomplish the following goals:

- Refactoring to a non-blocking operation.
- Migration to a concurrent execution model using protothreads.

The Atmega162 micro-processor offers the following ISRs for receiving and sending data via the UART ([7]):

- SIG_USART_RECV: Is being invoked, when the UDR register contains a new byte received from the UART.
- SIG_USART_DATA: Is being invoked, when the UDR register is ready to be filled with a byte to be transmitted via the UART.

So we have the possibility to send or receive data asynchronously from the main loop in the context of a concurrent execution model by using ISRs. Filling the UDR or reading the UDR in the main loop (and thus blocking it) is actually not necessary at all. The main loop can communicate with the ISRs through a receiving and transmitting queue buffer where it writes data to the transmitting queue and reads data from the receiving queue.

Using this sort of communication is known as the "producer-consumer problem". It can be implemented using a FIFO buffer. The Linux kernel (see [8] chapter 5.7.1) as well as (embedded) DSP micro-controllers (see [9]) use a very elegant FIFO-algorithm by providing a lock-free buffer being called "circular buffer" or "ring buffer".

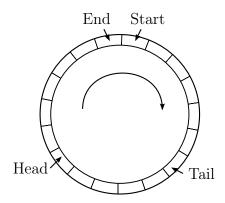

Figure 5.5. Illustration of a ring buffer

Figure 5.5 shows the basic principle of the algorithm. A circular buffer is defined by the following four pointers:

- **Start:** This pointer defines the beginning of the buffer in memory. This pointer is static.
- End: This pointer defines the end of the buffer in memory. It can also be expressed as the maximum length of the buffer. This pointer is static.
- **Head:** The head pointer is being changed dynamically by the producer. Whenever the producer wants to write data in the buffer the head pointer is increased and the corresponding memory filled. If the head points to the same address as the tail pointer the buffer is full or empty.
- Tail: The tail pointer is being changed dynamically by the consumer. Whenever the consumer wants to read data from the buffer the tail pointer is increased and the corresponding memory cleared. If the tail points to the same address as the head pointer the buffer is full or empty.

In order to distinguish whether the buffer is full or empty an additional size variable was implemented. The biggest advantage of the presented algorithm is the possibility to write and read data in a lock-free fashion. A consumer thread does not need to wait for a mutual exclusion on the buffer since the consumer thread is the only instance manipulating the tail pointer. The same applies for the producer being the only instance manipulating the head pointer.

The complete listing of the ring-buffer implementation can be seen in appendix A in the file src/ringbuf.c. There are two functions provided:

- ringbuf_add: This function is being called by the producer. The function immediately returns true if a byte could be written to the the buffer or false if the buffer is full.
- ringbuf_remove: This function is being called by the consumer. The function immediately returns true if a byte could read from the buffer or false if the buffer is empty.

The important nature of the above mentioned functions is that they are non-blocking because they return immediately. These functions could therefore be called from protothreads. A producer protothread running in the context of the main loop can write data like presented in listing 5.6. The consumer of this data is the SIG USART DATA ISR as presented in listing 5.7.

Listing 5.6. Producer writing data

```
PT_THREAD(producer(uint8_t data))
{
    PT_BEGIN(&pt);
    PT_WAIT_UNTIL(&pt, ringbuf_add(buf, data));
    PT_END(&pt);
}

    Listing 5.7. Consumer reading data

ISR(SIG_USART_DATA)
{
    uint8_t c;
    if (ringbuf_remove(buf, &c)) {
        UDR = c;
    }
}
```

Instead of *physically* blocking the algorithm expressed in listing 5.6 only *logically* blocks the protothread. If the buffer is full a context-switch back to the main loop is performed. The main loop sequentially executes all other concurrent modules and returns to the protothread which then again tries to add data into the ring buffer.
